

On the Complexity of Barrier Resilience for Fat Regions and Bounded Ply*

Matias Korman[†] Maarten Löffler[‡] Rodrigo I. Silveira[§]
Darren Strash[¶]

Abstract

In the *barrier resilience* problem (introduced by Kumar *et al.*, Wireless Networks 2007), we are given a collection of regions of the plane, acting as obstacles, and we would like to remove the minimum number of regions so that two fixed points can be connected without crossing any region. In this paper, we show that the problem is NP-hard when the collection only contains fat regions with bounded ply Δ (even when they are axis-aligned rectangles of aspect ratio $1 : (1 + \varepsilon)$). We also show that the problem is fixed-parameter tractable (FPT) for unit disks and for similarly-sized β -fat regions with bounded ply Δ and $O(1)$ pairwise boundary intersections. We then use our FPT algorithm to construct an $(1 + \varepsilon)$ -approximation algorithm that runs in $O(2^{f(\Delta, \varepsilon, \beta)} n^5)$ time, where $f \in O(\frac{\Delta^4 \beta^8}{\varepsilon^4} \log(\beta \Delta / \varepsilon))$.

1 Introduction

The *barrier resilience* problem asks for the minimum number of spatial regions from a collection \mathcal{D} that need to be removed, such that two given points p and q are in the same connected component of the complement of the union of the remaining regions. This problem was posed originally in 2005 by Kumar *et al.* [15, 16], motivated from sensor networks. In their formulation, the regions are unit disks (sensors) in some rectangular strip $B \subset \mathbb{R}^2$, where each sensor is able to detect movement inside its disk. The question is then how many sensors need to fail before an entity can move undetected from one side of the strip to the opposite one (that is, how *resilient* to failure the sensor system is). Kumar

*A preliminary version of this work appeared at the 9th International Symposium on Algorithms and Experiments for Sensor Systems, Wireless Networks and Distributed Robotics [14].

2 *et al.* present a polynomial time algorithm to compute the resilience in this case.
3 They also consider the case where the regions are disks in an annulus, but their
4 approach cannot be used in that setting.

5 1.1 Related Work

6 Despite the seemingly small change from a rectangular strip to an annulus, the
7 second problem still remains open, even for the case in which regions are unit
8 disks in \mathbb{R}^2 . There has been partial progress towards settling the question: Bereg
9 and Kirkpatrick [3] present a factor 5/3-approximation algorithm for the unit
10 disk case. This result was very recently improved to a 1.5-approximation by
11 Chan and Kirkpatrick [5]. On the negative side, Alt *et al.* [2], Tseng and Kirk-
12 patrick [23], and Yang [26, Section 5.1] independently showed that if the regions
13 are line segments in \mathbb{R}^2 , the problem is NP-hard. Tseng and Kirkpatrick [23]
14 also sketched how to extend their proof for the case in which the input consists
15 of (translated and rotated) copies of a fixed square or ellipse.

16 The problem of covering barriers with sensors has received a lot of attention
17 in the sensor network community (e.g., [6, 7, 12]). In the algorithms community,
18 closely related problems involving region intersection graphs have also become
19 quite popular. Gibson *et al.* [11] study a problem that is, in a sense, opposite of
20 ours: given a set of points and disks separating them (i.e., every path between
21 two points intersects some disk), compute the maximum number of disks one
22 can remove while keeping the points separated. They present a constant-factor
23 approximation algorithm for this problem. Later, Penninger and Vigan showed
24 that the problem is NP-complete [21]. Recently, Cabello and Giannopoulos [4]
25 gave a cubic-time algorithm for the case where only two points have to be kept
26 separated, for barriers that are arbitrary connected curves (under some mild
27 assumptions).

28 1.2 Results

29 We present constructive results for two natural restricted variants of the prob-
30 lem. In Section 3 we show that the problem is fixed-parameter tractable on
31 the resilience when the regions are unit disks. We then extend this approach to
32 other shapes that resemble unit disks. This resemblance is measured with the
33 following three restrictions: all regions are of similar size, region boundaries have
34 $O(1)$ pairwise intersections, and the collection of regions have bounded *ply* [19]
35 (that is, no point of the plane is covered by too many sensors). Such restrictions
36 are similar in spirit to previous results that bound the union complexity of fat
37 (and non-fat) regions [8, 9, 24]. Formal definitions of fatness, ply, and more
38 detailed descriptions of our restrictions are given in Section 3.2. In Section 4 we
39 also show that the FPT result can be used to obtain an approximation scheme.
40 In particular, the constructive results apply to the original unit disk coverage
41 setting when the collection of disks (or in general fat objects) has bounded ply.

42 As a complement to these algorithms, in Section 5 we show that the problem
1 is NP-hard even when the input is a collection of fat regions of arbitrary shape in

2 \mathbb{R}^2 . The result holds even if regions consist of axis-aligned rectangles of aspect
3 ratio $1 : 1 + \varepsilon$ and $1 + \varepsilon : 1$. Our results rely on tools and techniques from both
4 computational geometry and graph theory.

5 2 Preliminaries

6 We denote with p and q the points that need to be connected, and with \mathcal{D} the
7 set of regions that represent the sensors. To simplify the presentation of our
8 results, we make the following general position assumption: all intersections
9 between boundaries of regions in \mathcal{D} consist of isolated points. We say that a
10 collection of objects in the plane are *pseudodisks* if the boundaries of any two of
11 them intersect at most twice.

12 We formally define the concepts of *resilience* and *thickness* introduced in [3].
13 The *resilience of a path* π between two points p and q , denoted $r(\pi)$, is the
14 number of regions of \mathcal{D} intersected by π . Given two points p and q , the *resilience*
15 *of p and q* , denoted $r(p, q)$, is the minimum resilience over all paths connecting
16 p and q . In other words, the resilience between p and q is the minimum number
17 of regions of \mathcal{D} that need to be removed to have a path between p and q that
18 does not intersect any region of \mathcal{D} . Note that sometimes we will assume that
19 neither p nor q are contained in any region of \mathcal{D} , since such regions must always
20 be counted in the minimum resilience paths, hence we can ignore them (and
21 update the resilience we obtain accordingly).

22 Often it will be useful to refer to the arrangement (i.e., the subdivision of
23 the plane into faces; see [18, Section 6.2] for a formal definition) induced by the
24 regions of \mathcal{D} , which we denote by $\mathcal{A}(\mathcal{D})$. Based on this arrangement we define a
25 weighted dual graph $G_{\mathcal{A}(\mathcal{D})}$ as follows (refer to Figure 1). There is one vertex for
26 each face (i.e., 2-dimensional cell) of $\mathcal{A}(\mathcal{D})$. Each pair of neighboring cells A, B
27 is connected in $G_{\mathcal{A}(\mathcal{D})}$ by two directed edges, (A, B) and (B, A) . The weight of
28 an edge is 1 if, when traversing from the starting cell to the destination one, we
29 enter a region of \mathcal{D} (or 0 if we leave a region¹).

30 The *thickness* of a path π between p and q , denoted $t(\pi)$, equals the number
31 of times π enters a region of \mathcal{D} when traveling from p to q (possibly counting
32 the same region multiple times). Given two points p and q , the *thickness of p*
33 *and q* , denoted $t(p, q)$, is the value $|\mathfrak{P}_{G_{\mathcal{A}(\mathcal{D})}}(p, q)| + \Delta(p)$, where $\mathfrak{P}_{G_{\mathcal{A}(\mathcal{D})}}(p, q)$ is
34 a shortest path in $G_{\mathcal{A}(\mathcal{D})}$ from the cell of p to the cell of q , and $\Delta(p)$ equals the
35 number of regions that contain p . Also note that the resilience (or thickness)
36 between two points only depends on the cells to which the points belong. Hence,
37 we can naturally extend the definitions of thickness to encompass two cells of
38 $\mathcal{A}(\mathcal{D})$, or a cell and a point. Unless otherwise stated, we will use ρ to denote a
39 path with minimum resilience, and τ for one of minimum thickness.

40 Note that thickness and resilience can be different (since entering the same
41 region several times has no impact on the resilience, but is counted every time
1 for the thickness). In fact, the thickness between two points can be efficiently

¹Note that no other option is possible under our general position assumption.

Figure 1: The graph $G_{A(D)}$ for an arrangement of three disks. Solid edges have weight 1, dashed edges have weight 0.

Figure 2: (a) With n unit disks and one arbitrarily large disk (orange), the optimal tour may be forced to enter and leave the same region up to $\Omega(n)$ times, even when the ply of the disks is at most 3. (b) When we move the yellow disks closer together, the radius of the orange disk can be made arbitrarily close to 1, at the cost of increasing the ply (i.e., having many disks covering the same point).

2 computed in polynomial time using any shortest path algorithm for weighted
3 graphs (for example, using Dijkstra's algorithm). However, as we will see later,
4 the thickness (and the associated shortest path) will help us find a path of low
5 resilience.

6 Throughout the paper we often use the following fundamental property of
7 disks, already observed in [3]. In the statement below, “well-separated” is in
8 the sense used in [3]—that is, the distance between p and q is at least $2\sqrt{3}$.²

9 **Lemma 1 ([3], Lemma 1)** *Let \mathcal{D} be a set of unit disks, and let ρ be a path*
10 *from p to q of minimum resilience. If p, q are well-separated, then ρ encounters*
11 *no disk of \mathcal{D} more than twice.*

12 **Corollary 1 ([3])** *When the regions of \mathcal{D} are unit disks, the thickness between*
13 *two well-separated points is at most twice their resilience.*

²Note that the well-separatedness of p and q is used to prove a factor 2 instead of 3. Everything still works for points that are not well-separated, at a slight increase of the constants. Our most general statements for β -fat regions do not make this requirement.

14 Note that a crucial property in the above results is that all disks have the same
15 size. In Figure 2(a) we show problem instances with a single large disk that has
16 to be traversed a linear number of times in any minimum resilience path. The
17 same instance is then modified in Figure 2(b) so that the radius of the larger
18 disk is only $1 + \varepsilon$ times larger than the radius of the other disks (at the expense
19 of concentrating all disks at the same point).

20 3 Fixed-parameter tractability

21 In this section we introduce a single-exponential fixed-parameter tractable (FPT)
22 algorithm, where the parameter is the resilience of the optimal solution. Thus,
23 our aim is to obtain an algorithm that given a problem instance, determines
24 whether or not there is a path of resilience r between p and q , and runs in
1 $O(2^{f(r)}n^c)$ time for some constant c and some polynomial function f .

2 For clarity we first explain the algorithm for the special case of unit disks.
3 Afterwards, in Section 3.2, we show how to adapt the solution to the case in
4 which \mathcal{D} is a collection of β -fat objects. Note that for treating the case of
5 unit disk regions we assume that p and q are well-separated, so we can apply
6 Lemma 1. This requirement is afterwards removed in Section 3.2.

7 First we give a quick overview of the method of Kumar *et al.* [15] for open belt
8 regions. Their idea consists of considering the intersection graph of \mathcal{D} together
9 with two additional artificial vertices s_a, t_a with some predefined adjacencies.
10 There is a path from the bottom side to the top side of the belt if and only if
11 there is no path between s_a and t_a in the graph. Hence, computing the resilience
12 of the network is equal to finding a minimum vertex cut between s_a and t_a .

13 We start by giving a bird's-eye view of our algorithm. Let ρ be a path of
14 minimum resilience from p to q , and let π be any known path that starts at
15 p , passes through q , and reaches an unbounded region. Assume that somehow
16 we know that ρ and π do not cross (other than at p and q). Then, we can cut
17 open through π effectively splitting the regions of $\mathcal{A}(\mathcal{D})$ traversed by the path
18 into two. Topologically speaking, we get something that is homeomorphic to
19 an open belt region, and thus we can solve the problem as such: construct the
20 intersection graph, connect the split regions of $\mathcal{A}(\mathcal{D})$ to either of the artificial
21 vertices depending on which side of the cut they lie in, and look for a minimum
22 vertex cut (see Figure 3, left). Note that, when doing this cut, it is possible that
23 a disk is split into more than one component. Whenever this happens, we must
24 identify the portions as one (i.e., when one portion is entered, then entering the
25 other portions of the same disk is *for free*).

26 Thus, the problem is easy once we have a path π that does not cross with ρ .
27 Unfortunately, finding such a path is difficult. Instead, we use several observa-
28 tions to compute a (possibly non-simple) path that cannot have many crossings
29 with ρ , and guess where (if any) these crossings happen. Naturally, we don't
30 know the way in which the two paths interact, but we will try all possibilities
31 and return the one whose resulting resilience is smallest. A fixed crossing pat-
1 tern decomposes ρ into subpaths whose endpoints are in π (see Figure 3, right).

Figure 3: (left) If we are given an infinitely long path π (in black in the figure) that goes through p and q , and is not crossed by ρ , we can cut open through it and obtain an open belt instance. The resulting graph (with the artificial vertices) is shown for clarity. (right) When the two paths intersect (ρ denoted with a dashed path) we obtain several open belt problem instances. However, these problems are not independent, since the removal of the highlighted disk makes the paths from p to m and from m to q feasible.

2 Although the subpaths are unknown, we can compute them via the usual open
3 belt region approach. The main problem is that the different sub-problems are
4 not independent (removing a single region may be useful for several subpaths).
5 Thus, rather than finding a vertex cut that isolates the single source to the
6 single sink, we are given a list of sources and sinks that need to be pairwise
7 disconnected from each other. In the literature, this problem is known as the
8 *vertex multicut problem* [25], and several FPT approaches are known.

9 We now present some observations that will allow us to have a nice choice of
10 π (i.e., find a path in which the number of crossings with ρ does not depend on
11 n). Consider a minimum resilience path ρ of shortest length between the cells
12 containing p and q in $G_{\mathcal{A}(\mathcal{D})}$, and let t be the number of disks traversed by ρ .
13 Since ρ has shortest length, it does not enter and leave the same region unless it
14 helps reduce resilience. Since we assumed that p is not contained in any region,
15 t is exactly the thickness of p and q . We observe that cells with high thickness
16 to p or q can be ignored when we look for low resilience paths.

17 **Lemma 2** *The minimum resilience path ρ between p and q cannot traverse cells*
18 *whose thickness to p or q is larger than $1.5t$.*

19 **Proof:** We argue about thickness to p ; the argument with respect to q is
20 analogous. Let ρ be a path of minimum resilience between p and q , and let r be
21 the resilience of ρ . Also, let τ be a minimum-thickness path from p to q . Recall
22 that ρ does not enter a disk more than twice, hence the thickness of ρ is at most
23 $2r \leq 2t$. Assume, for the sake of contradiction, that the thickness of some cell
24 C traversed by ρ is greater than $1.5t$. Let ρ_C be the portion of ρ from C to
25 q . Since the thickness of ρ from p to q is at most $2t$, the triangular inequality
1 implies that the thickness of ρ_C is less than $0.5t$.

Figure 4: In order to transform our problem to one that resembles an open belt, we remove all cells of high thickness and cut through the tree formed by the union of two shortest paths. Figures (a) and (b) show two examples of the result.

2 Now, by concatenating τ and ρ_C , we would obtain a path that connects
3 p with C whose thickness is less than $1.5t$, giving a contradiction with the
4 thickness of cell C . \square

5 For simplicity in the exposition, we will also bound the region to consider
6 (thus, we discard regions with very high resilience since they will not be traversed
7 by ρ). Let R be the union of the cells of the arrangement that have thickness
8 from p at most $1.5t$; we call R the *domain* of the problem. Observe that R is
9 connected, but need not be simple (see Figure 4(a)).

10 For simplicity in the explanation, we add additional discs surrounding \mathcal{D} so
11 as to make sure that the unbounded face has thickness more than $1.5t$. This does
12 not affect the asymptotic behavior of our algorithm, but it removes the need of
13 considering some degenerate situations. Note that the number of cells remaining
14 in R might still be quadratic, hence asymptotically speaking the instance size
15 has not decreased (the purpose of this pruning will become clear later).

16 **Lemma 3** *There exists a point q' on the outer boundary of R and a tree that*
17 *spans p , q , and q' that has total thickness³ $2.5t$.*

18 **Proof:** Pick any point q' in the outer boundary of R and consider the tree
19 obtained by joining the shortest paths from q' to p , and p to q . Note that
20 the two paths may go through the same cell of R , see Figure 4(a). The exact
21 paths chosen are not important provided that they have no proper crossings.
22 By definition, the thickness of each of these paths cannot exceed $1.5t$ and t ,
1 respectively, hence the lemma is shown. \square

³The thickness of the tree is defined as the thickness of the paths that compose the tree.

Figure 5: (a) Illustration of the situation in Figure 4(b) after cutting along π . We get the domain R' , add a set S of extra vertices on the boundary of R' , and end up with two copies of q . A crossing pattern, consisting of a topological path ρ (defined by the sequence of points of S it passes). The disks of \mathcal{D} intersected by π are shown green if they are crossed by ρ , and orange otherwise. (b) Domain after removing the disks traversed by π that are not crossed by ρ . The green disk (shown transparent) is added to the solution, and thus ignored from now on.

2 Let π be the path from q' to q' that traverses the tree from the previous
3 lemma. We “cut open” through π , removing it from our domain. Note that
4 cells that are traversed by π are split into two copies (or even three, if the tree
5 has a vertex of degree three) of the same Jordan curve, see Figure 5(a).

6 Consider now a minimum resilience path ρ , and let $r = r(\rho)$ denote its
7 resilience. This path can cross π several times, and it can even coincide with
8 π in some parts (shared subpaths). Although we do not know how and where
9 these crossings occur, we can *guess* (i.e., try all possibilities) the topology of ρ
10 with respect to π . For each disk that π passes through, we consider two cases:
11 if ρ goes through it, it will be part of the solution, and can be ignored from now
12 on (increasing by one the total resilience). Otherwise, we make it an obstacle,
13 removing it from the domain, see Figure 5(b). In that way we know the exact
14 behavior of ρ in the regions traversed by π . Additionally, we guess how many
15 times ρ and π share part of their paths (either for a single crossing in one cell,
16 or for a longer shared subpath). For each shared subpath, we guess from which
17 cell ρ arrives and leaves.

18 We call each such configuration a *crossing pattern* between π and ρ . More
19 formally, a single crossing is described by a tuple of four cells: the first cell
20 C that the two paths have in common for that crossing, the cell that ρ visits
21 right before entering C . Similarly, we add the last cell that the two paths have
22 in common and the cell that is afterwards entered by ρ . A crossing pattern is
1 described by a sorted list of all the crossings that π and ρ have.

2 **Lemma 4** *For any problem instance \mathcal{D} , there are at most $2^{4r \log r + o(r \log r)}$ cross-*
3 *ing patterns between π and ρ , where $r = r(\rho)$.*

4 **Proof:** First, for all disks in π , we guess whether or not they are also traversed
5 by ρ . By Lemma 3, π has thickness at most $2.5t$, there are at most such many
6 disks (hence up to $2^{2.5t}$ choices for which disks are traversed by ρ).

7 Now observe that π cannot traverse many cells of $\mathcal{A}(\mathcal{D})$: when moving from
8 a cell to an adjacent one, we either enter or leave a disk of \mathcal{D} . Since we cannot
9 leave a disk we have not entered and π has thickness at most $2.5t$, we conclude
10 that at most $5t$ cells will be traversed by π (other than the starting and ending
11 cells).

12 We now bound the number of (maximal) shared subpaths between ρ and π :
13 recall that ρ passes through exactly $r = r(\rho)$ disks, and visits each disk at most
14 twice. Hence, there cannot be more than $2r$ shared subpaths. For each shared
15 subpath we must pick two of the cells traversed in π (as candidates for first
16 and last cell in the subpath). By the previous observation there are at most
17 $5t$ candidates for first and last cell (since that is the maximum number of cells
18 traversed by π). Additionally, for each shared subpath we must determine from
19 which side ρ entered and left the subpath; in most cases we have two options
20 for entering and leaving (since most cells are split into two by π). However, it
21 could happen that the first, last (or even both cells) are the cell containing m .
22 The cell containing m was split into three, and thus we have three options on
23 which part of the cell ρ enters or leaves. That is, on the worst case there are
24 three possibilities where ρ enters and three possibilities where ρ leaves the path,
25 which gives a total of nine options overall. Since these choices are independent,
26 in total we have at most $2r \times (5t \times 5t \times 9)^{2r} = 101250^r \cdot t^{4r} r$ possibilities.

27 That is, in order to determine a crossing pattern, we must fix which disks of
28 π are traversed by ρ as well as how many and where do the crossings between ρ
29 and π happen. The bounds for each of these terms are $2^{2.5t}$ and $101250^r \cdot t^{4r} r$,
30 respectively. Since these choices are independent, and using the fact that $t \leq 2r$,
31 we obtain:

$$\begin{aligned} 2^{2.5t} \cdot 101250^r \cdot t^{4r} r &\leq 2^{5r} \cdot 101250^r \cdot (2r)^{4r} r \\ &= 2^{5r + r \log 101250 + 4r \log 2r + \log r} \\ &= 2^{4r \log r + o(r \log r)} \end{aligned}$$

32 □
33 Note that the bound is very loose, since most of the choices will lead to an
34 invalid crossing pattern. However, the importance of the lemma is in the fact
35 that the total number of crossing patterns only depends on r .

36 Our FPT algorithm works by considering all possible crossing patterns, find-
37 ing the optimal solution for a fixed crossing pattern, and returning the solution
38 of smallest resilience. From now on, we assume that a given pattern has been
39 fixed, and we want to obtain the path of smallest resilience that satisfies the
1 given pattern. If no path exists, we simply discard it and associate infinite
2 resilience to it.

Figure 6: (a) We may schematically represent W as a circle, since the geometry no longer plays a role. Partial paths are dashed (note that we do not know through which disks these paths will traverse). (b) The intersection graph of the regions after adding extra vertices for boundary pieces between points of $S \cup \{p, q\}$, shown in green. (c) The secondary graph H , representing the forbidden pairs. (d) A possible solution of the vertex multicut problem (highlighted in orange). (e) The corresponding cut for the original problem. Once the orange disks have been removed, the endpoints of the partial paths belong to the same region, and thus we can connect them without entering any additional disk (solid paths).

3.1 Solving the problem for a fixed crossing pattern

Recall that the crossing pattern gives us information on how to deal with the disks traversed by π . Thus, we remove all cells of the arrangement that contain one or more disks that are forbidden to ρ . Similarly, we remove from \mathcal{D} the disks that ρ must cross. After this removal, several cells of our domain may be merged.

Since we do not use the geometry, we may represent our domain by a disk W (possibly with holes). After the transformation, each remaining region of \mathcal{D} becomes a pseudodisk, and ρ becomes a collection of disjoint partial paths, each of which has its endpoints on the boundary of W (see Figure 6(a)), but is otherwise not yet fixed. To solve the subproblem associated with the crossing pattern we must remove the minimum number of disks so that all partial paths are feasible.

We consider the intersection graph G_I between the remaining regions of \mathcal{D} . That is, each vertex represents a region of \mathcal{D} , and two vertices are adjacent if and only if their corresponding regions intersect. Similarly to [15], we must augment

the graph with boundary vertices. The partial paths split the boundary of R into several components. We add a vertex for each component (these vertices are called *boundary vertices*). We connect each such vertex to vertices corresponding to pseudodisks that are adjacent to that piece of boundary (Figure 6(b)). Let $G_{\mathcal{X}} = (V_{\mathcal{X}}, E_{\mathcal{X}})$ be the resulting graph associated to crossing pattern \mathcal{X} . Note that no two boundary vertices are adjacent.

We now create a secondary graph H as follows: the vertices of H are the boundary vertices of $G_{\mathcal{X}}$. We add an edge between two vertices if there is a partial path that separates the vertices in $G_{\mathcal{X}}$ (Figure 6(c)). Two vertices connected by an edge of H are said to form a *forbidden pair* (each partial path that would create the edge is called a *witness* partial path). We first give a bound on the number of forbidden pairs that H can have.

Lemma 5 *Any crossing pattern has at most $2r^2 + r$ forbidden pairs.*

Proof: By definition, $G_{\mathcal{X}}$ only adds edges between boundary vertices. Thus, it suffices to show that $G_{\mathcal{X}}$ has at most $2r + 1$ boundary vertices. Since partial paths cannot cross, each such path creates a single cut of the domain. This cut introduces a single additional boundary vertex (except the first partial path that introduces two vertices). Recall that we can map the partial paths to crossings between paths π and ρ and, as argued in the proof of Lemma 4, these paths can cross at most $2r$ times. Thus, we conclude that there cannot be more than $2r + 1$ boundary vertices. \square

The following lemma shows the relationship between the vertex multicut problem and the minimum resilience path for a fixed pattern.

Lemma 6 *There are k vertices of $G_{\mathcal{X}}$ whose removal disconnects all forbidden pairs if and only if there are k disks in \mathcal{D} whose removal creates a path between p and q that obeys the crossing pattern \mathcal{X} .*

Proof: Consider the regions of $\mathcal{A}(\mathcal{D})$ inside R that are not covered by any disk after the k disks have been removed and let R' be their union. By definition, there is a path between p and q with the fixed crossing pattern if all partial paths are feasible (i.e., there exists a path connecting the two endpoints that is totally within R'). The reasoning for each partial path is analogous to the one used by Kumar *et al.* [15]. If all partial paths are possible, then no forbidden pair can remain connected in $G_{\mathcal{X}}$, since—by definition—each forbidden pair disconnects at least one partial path (the witness path). On the other hand, as soon as one forbidden pair remains connected, there must exist at least one partial path (the witness path) that crosses the forbidden pair. Thus if a forbidden path is not disconnected, there can be no path connecting p and q for that crossing pattern. \square

Using Lemma 6, we can transform the barrier resilience problem to the following one: given two graphs $G = (V, E)$, and $H = (V, E')$ on the same vertex set, find a set $D \subset V$ of minimum size so that no pair $(u, v) \in E'$ is connected in $G \setminus D$. This problem is known as the (vertex) *multicut* problem [25]. Although the problem is known to be NP-hard if $|E'| > 2$ [13], there exist several

4 FPT algorithms on the size of the cut and on the size of the set E' [17, 25].
5 Among them, we distinguish the method of Xiao ([25], Theorem 5) that solves
6 the vertex multicut problem in roughly $O((2k)^{k+\ell/2}n^3)$ time, where k is the
7 number of vertices to delete, $\ell = |E'|$, and n is the number of vertices of G .

8 **Theorem 1** *Let \mathcal{D} be a collection of unit disks in \mathbb{R}^2 , and let p and q be two*
9 *well-separated points. There exists an algorithm to test whether $r(p, q) \leq r$, for*
10 *any value r , and if so, to compute a path with that resilience, in $O(2^{f(r)}n^3)$*
11 *time, where $f(r) = r^2 \log r + o(r^2 \log r)$.*

12 **Proof:** Recall that our algorithm considers all possible crossings between ρ
13 and π . For any fixed crossing pattern \mathcal{X} , our algorithm computes $G_{\mathcal{X}}$, and
14 all associated forbidden pairs. We then execute Xiao's FPT algorithm [25] for
15 solving the vertex multicut problem. By Lemma 6, the number of removed
16 vertices (plus the number of disks that were forced to be deleted by \mathcal{X}) will give
17 the minimum resilience associated with \mathcal{X} .

18 Regarding the running time, the most expensive part of the algorithm is
19 running an instance of the vertex multicut problem for each possible crossing
20 pattern. Observe that the parameters k and ℓ of the vertex multicut problem
21 are bounded by functions of r as follows: $k \leq r$ and $\ell \leq 2r^2 + r$ (the first
22 claim is direct from the definition of resilience, and the second one follows from
23 Lemma 5). Hence, a single instance of the vertex multicut problem will need
24 $O((2r)^{r+(2r^2+r)/2}n^3) = O(2^{(1+\log r)(r^2+1.5r)}n^3) = O(2^{r^2 \log r + o(r^2 \log r)}n^3)$ time.
25 By Lemma 4 the number of crossing patterns is bounded by $2^{4r \log r + o(r \log r)}$.
26 Thus, by multiplying both expressions we obtain the bound on the running
27 time, and the theorem is shown. \square

28 We remark that the importance of this result lies in the fact that an FPT
29 algorithm exists. Hence, although the dependency on r is high, we emphasize
30 that the bounds are rather loose. We also note that both the minimum resilience
31 path and the disks to be deleted can be reported.

32 3.2 Extension to Fat Regions

33 We now generalize the algorithm to consider more general shapes. A region
34 D is β -fat if there exist two concentric disks C and C' whose radii differ by
35 at most a factor β , such that $C \subseteq D \subseteq C'$ (whenever the constant β is not
36 important, the region D is simply called *fat*). Figure 7 shows an example of a
37 2-fat region. However, for our algorithms, it is not sufficient for us to assume
38 that the regions are fat. We impose three restrictions on our fat regions, which
39 make them more like disks: (1) the collection of regions has bounded ply Δ ,
40 (2) all regions have similar size, allowing us to assume the radius of C is 1, and
41 the radius of C' is β , and (3) any two regions have $O(1)$ intersections between
42 their boundaries. Together, these three restrictions ensure that no minimum
1 resilience path traverses a given region more than a constant number of times,
2 making thickness within a constant factor of resilience. We formally describe
3 each restriction, and illustrate how its removal impacts the path complexity.

Figure 7: A β -fat region D is contained in a big disk, but contains a smaller disk; in this example, $\beta = 2$.

Figure 8: If we eliminate any one of our restrictions we can construct a problem instance whose minimum resilience path must leave and reenter the same (orange) region $\Theta(n)$ times. Here are constructions when removing one of our three restrictions: (a) bounded ply, and (b) bounded region complexity. Note that the case of distinct size was already discussed in Figures 2(a) and 2(b).

4 **Bounded ply** The arrangement formed by a collection of regions \mathcal{D} is said
5 to have bounded ply Δ if no point $p \in \mathbb{R}^2$ is contained in more than Δ
6 elements of \mathcal{D} . As we illustrate in Figure 8(a), we can place regions of
7 similar size and bounded region complexity (but no bounded ply) forming
8 a corridor. In particular, the minimum resilience path between s and t may
9 be forced to leave and reenter another similarly-sized region $\Theta(n)$ times.
10 Note that this construction is not possible for unit disks, and therefore
11 unit disk instances do not require bounded ply; however, as soon as we
12 allow a disk with larger radius (e.g., a disk of radius $1 + \epsilon$, $\epsilon > 0$), the
13 bounded ply restriction is required.

14 **Similar size** We assume without loss of generality that the radius of C is 1
15 and the radius of C' is β ; in this case we will call D a β -fat unit region. As
1 previously shown in Figures 2(a) and 2(b), with the existence of a single
2 larger region we can create a corridor of $\Theta(n)$ small interlocking regions
3 with constant ply, and partially cover it with a large region to force the

4 optimal resilience path to leave and reenter the large region $\Theta(n)$ times.

5 **Bounded region complexity** Our final assumption is that the fat regions
6 cannot be too complex. In particular, we assume that any two region
7 boundaries have $O(1)$ pairwise intersections, ensuring that the intersection
8 between any two regions has $O(1)$ connected components. As shown in
9 Figure 8(b), we can create a corridor with two regions that have $\Theta(n)$
10 pairwise boundary intersections with a third region, forcing the minimum
11 resilience path to leave and reenter this third region $\Theta(n)$ times. Note that
12 such complex regions can be formed, for example, by taking the union of
13 $\Theta(n)$ circles with radius 1, with centers that are spaced $(\beta - 1)/n$ apart
14 on a line.

15 Although these restrictions may seem excessive, previous results have made
16 similar assumptions on input regions, and for the same reason we do here: worst-
17 case configurations are possible even with the simplest inputs. For example, to
18 bound the union complexity of fat (α, β) -covered regions, Efrat [9] assumes con-
19 stant *algebraic complexity*—that region boundaries can be represented by $O(1)$
20 algebraic polynomials, implying that the region boundaries have at most $O(1)$
21 pairwise intersections. Whitesides and Zhao [24], when defining *k-admissible*
22 curves, impose further restrictions on their (non-fat) regions, requiring the dif-
23 ference of any two regions to be connected, in order to guarantee linear-size
24 union boundary (see also [1, 20] for alternative proofs of this result). Lastly,
25 de Berg [8] assumes constant density, which bounds the number of regions that
26 can intersect any small disk, similar in spirit to ply.

27 To our knowledge, no definition of fatness meets any of our three assump-
28 tions. Fortunately, our assumptions are not overly restrictive. Indeed, they
29 are representative of cases that we are likely to encounter in practice, as it is
30 inefficient to place sensors so that many of them cover the same region, sen-
31 sor ranges are typically of similar size, and limiting the boundary intersections
32 encompasses both unit disks and pseudodisks as special cases.

33 The main workings of the algorithm remain unchanged. We start by extend-
34 ing Lemmas 1, 2, 3, 4 and 5 to consider β -fat unit regions.

35 **Lemma 7** *Let \mathcal{D} be a set of β -fat unit regions forming an arrangement with*
36 *ply Δ , and bounded region complexity. Let $S \subset \mathcal{D}$ be an optimal solution. In*
37 *the sequence of regions of S found when going from p to q in an optimal way,*
38 *no region of S appears more than $O((2\beta + 1)^2 \Delta)$ times.*

39 **Proof:** Let D be a region in S , and consider its containing disk C' with
40 center c . Analogously to the original argument by Bereg and Kirkpatrick [3],
41 we note that every time the optimal path visits and leaves D , it must do so
42 to avoid some other region. This other region must intersect D , and since it is
1 β -fat unit, it must contain a unit disk centered at distance at most β from D .

2 Therefore all regions intersecting D have their unit-disks centered at distance
3 at most 2β from c . In particular, their unit-disks are totally contained in a disk
4 of radius $2\beta + 1$ centered at c . A simple area argument shows that at most

Figure 9: Example showing we can have $\Theta(\beta^2)$ pairwise disjoint β -fat regions (in orange) that intersect a fixed region (green). Most orange regions consist of the union of a disk and a thin curve-like shape. By placing a constant number of regions, we can force the minimum resilience path to follow around the boundary of the green region, causing it to enter and leave $\Omega(\beta^2)$ times. This construction has overall constant ply, so we can repeat it until we reach the maximum ply Δ and get the $\Omega(\Delta\beta^2)$ lower bound

5 $(2\beta + 1)^2$ disjoint unit-disks fit into a disk of radius $(2\beta + 1)$. Since the ply is
6 bounded by Δ , overall there can be up to $\Delta(2\beta + 1)^2$ regions intersecting D .
7 Recall that, by our fatness assumption, two regions can intersect only in $O(1)$
8 connected components. Therefore, the number of times an optimal path can
9 reenter region D is, proportional to the number of other regions that intersect
10 D which is bounded by $\Delta(2\beta + 1)^2$. \square

11 We note that our bound is asymptotically tight. Figure 9 illustrates how a
12 matching lower bound.

13 **Corollary 2** *When the regions of \mathcal{D} are β -fat unit regions forming an arrange-*
14 *ment with ply Δ , and bounded region complexity, the thickness between two*
15 *points is at most $\Delta(2\beta + 1)^2$ times their resilience.*

1 This change in the upper bound of the thickness in terms of the resilience
2 implies similar changes in Lemmas 2, 3, 4 and 5. The following lemmas sum-
3 marize these changes; they are proved in the same way as their counterparts for

4 disks, thus we only sketch the differences with the original proofs (if any).

5 **Lemma 8** *When the regions of \mathcal{D} are β -fat unit regions forming an arrange-*
6 *ment with ply Δ , and bounded region complexity, the minimum resilience path*
7 *between p and q cannot traverse cells whose thickness to p or q is larger than*
8 *$(1 + \Delta(2\beta + 1)^2)\frac{t}{2}$.*

9 **Proof:** We use the same reasoning as in the proof of Lemma 2. On the one
10 hand there is the minimum thickness path between p and q , whose thickness is
11 t . On the other hand, we also have the minimum resilience path ρ between the
12 same points, whose thickness is at most $\Delta(2\beta + 1)^2 t$ by Corollary 2. Assume
13 now that any cell C traversed by ρ has thickness $k\Delta(2\beta + 1)^2 t$ from p , for some
14 $0 < k < 1$. The alternative path goes from p to C , via q , and its thickness is at
15 most $(1 - k)\Delta(2\beta + 1)^2 t + t$. The bound we need is obtained for the value of k
16 that makes both expressions equal, which is $k = \frac{1}{2} + \frac{1}{2\Delta(2\beta + 1)^2}$, leading to the
17 claimed value. \square

18 Thus, for β -fat objects our domain R now becomes be the union of the cells
19 of the arrangement that have thickness from p at most $(1 + \Delta(2\beta + 1)^2)\frac{t}{2}$.

20 **Lemma 9** *There exists a point q' on the outer boundary of R and a tree that*
21 *spans p , q , and q' that has total thickness at most $(3 + \Delta(2\beta + 1)^2)\frac{t}{2}$.*

22 As before, we use π to denote the path from q' to q' that traverses the tree
23 from the previous lemma.

24 **Lemma 10** *For any problem instance \mathcal{D} , there are at most $2^{O(\Delta^2 \beta^4 r + \Delta \beta^2 r \log(\Delta \beta r))}$*
25 *crossing patterns between π and ρ .*

26 **Proof:** Let $\mu = \Delta(2\beta + 1)^2$ and $\nu = \frac{3 + \Delta(2\beta + 1)^2}{2}$. We proceed as in the proof
27 of Lemma 4. Recall that previously we had $2^{2.5t} \times 2r \cdot (5t \times 5t \times 9)^{2r}$ crossing
28 patterns, but now we must use the bounds that depend on β instead. What
29 before was $2r$ now becomes μr , and the $2.5t$ terms now become νt . Making these
30 changes in the previous expression, we obtain that the number of crossings is
31 bounded by

$$2^{\nu t} \times \mu r \times (2\nu t \times 2\nu t \times 9)^{\mu r}.$$

32 Since $t \leq \mu r$ (and by simplifying the expression), this is upper bounded by

$$2^{\nu \mu r} \times \mu r \times (6\nu \mu r)^{2\mu r} = 2^{\nu \mu r + \log(\mu r) + 2\mu r \log(6\nu \mu r)}.$$

33 Finally, we apply that both $\mu, \nu \in O(\Delta \beta^2)$, and obtain the desired bound.
34 \square

35 **Lemma 11** *Any crossing pattern has at most $O(\Delta^2 \beta^4 r^2)$ forbidden pairs.*

1 **Proof:** As in the unit disc case, each crossing between π and ρ creates an
2 additional vertex in the boundary (i.e., a potential vertex of H). Further note
3 that π and ρ can cross at most $2\mu r$ times (since they traverse through at most
4 that many cells of $\mathcal{A}(\mathcal{D})$). A bound on the number of vertices of H immediately
5 implies a quadratic bound on the number of edges in H as well. Thus, we obtain
6 that the number of forbidden pairs is at most $O((2\mu r + 1)^2) = O(\Delta^2 \beta^4 r^2)$ as
7 claimed. \square

8 With these results in place, the rest of the algorithm remains unchanged:
9 the only additional property of unit disks that we use is the fact that they
10 are connected, to be able to phrase the problem as a vertex cut in the region
11 intersection graph.

12 **Theorem 2** *Let \mathcal{D} be a collection of n connected β -fat unit regions of bounded*
13 *region complexity in \mathbb{R}^2 forming an arrangement of ply Δ , and let p and q be*
14 *two points. Let r be a parameter. There exists an algorithm to test whether*
15 *$r(p, q) \leq r$, and if so, to compute a path with that resilience, in $O(2^{f(\Delta, \beta, r)} n^3)$*
16 *time, where $f(\Delta, \beta, r) \in O(\Delta^2 \beta^4 r^2 \log(\Delta \beta r))$.*

17 **Proof:** As before, the running time is bounded by the product of the
18 number of crossing patterns and the time needed to solve a single instance
19 of the vertex multicut problem. By Lemmas 10 and 11, these bounds now
20 become $O(2^{O(\Delta^2 \beta^4 r + \Delta \beta^2 r \log(\Delta \beta r))})$ and $O(2^{O(\Delta^2 \beta^4 r^2 \log(\Delta \beta r))} n^3)$, respectively.
21 The product of both is dominated by the second term, hence the theorem is
22 shown. \square

23 4 $(1 + \varepsilon)$ -approximation

24 In this section we present an efficient polynomial-time approximation scheme
25 (EPTAS) for computing the resilience of an arrangement of disks of bounded
26 ply Δ . The general idea of the algorithm is very simple: first, we compute
27 all pairs of regions that can be reached by removing at most k disks, for $k =$
28 $\lceil (16\Delta - 12)/\varepsilon^2 \rceil$. Then, we compute a shortest path in the dual graph of the
29 arrangement of regions, augmented with some extra edges. We prove that the
30 length of the resulting path is a $(1 + \varepsilon)$ -approximation of the resilience.

31 As in the previous section, we first consider the case in which \mathcal{D} is a set of n
32 unit disks in \mathbb{R}^2 (note that this time we have the additional constraint that no
33 point is covered in more than Δ disks). Let $\mathcal{A}(\mathcal{D})$ be the arrangement induced
34 by the regions of \mathcal{D} , and let $G_{\mathcal{A}(\mathcal{D})}$ be the dual graph of $\mathcal{A}(\mathcal{D})$. Recall that
35 $G_{\mathcal{A}(\mathcal{D})}$ has a vertex for every cell of $\mathcal{A}(\mathcal{D})$, and a directed edge between all pairs
36 of adjacent cells of cost 1 when entering a disk, and cost 0 when leaving a disk.
37 For any given k , let G_k be the graph obtained from $G_{\mathcal{A}(\mathcal{D})}$ by adding, for each
38 pair of cells $A, B \in \mathcal{A}(\mathcal{D})$ with resilience at most k , a *shortcut edge* \overrightarrow{AB} of cost
39 $r(A, B)$.

40 For a pair of cells of $\mathcal{A}(\mathcal{D})$, we can test whether $r(A, B)$ is smaller than k ,
1 and if so, compute it, in $O(2^{f(k)} n^3)$ time (where $f(k) = k^2 \log k + o(k^2 \log k)$)

by applying Theorem 1 to a point $p \in A$ and a point $q \in B$. Since the number of pairs of cells of the arrangement is also bounded by a polynomial in n , we overall get a EPTAS since k is a constant that depends only on ε and Δ . Again, we emphasize that the bounds presented in this section are not tight, but our objective is to show the existence of an EPTAS for this problem.

4.1 Analysis

Lemma 12 *Let $D \in \mathcal{D}$, where $\mathcal{A}(\mathcal{D})$ has ply Δ , and let s, t be any two points inside D . Then the resilience between s and t in \mathcal{D} is at most $4\Delta - 3$.*

Proof: Let c be the number of disks that contain s or t (or both). Clearly these disks must be removed. Also notice that $c \leq 2\Delta - 1$, since D contains both points and no point is contained in more than Δ disks. Now we analyze how many other disks may need to be removed too.

Consider a minimum resilience path between s and t among those that stay inside D . For each disk D_1 (not containing neither s nor t) that needs to be removed in an optimal solution, there must be another disk D_2 that intersects D_1 , so that D_1 and D_2 together separate s and t inside D . We call such a pair of disks a *separating pair*. Thus if the resilience is $(c + c')$, there must be at least c' *disjoint*⁴ separating pairs intersecting D . Let a and b be the diametral pair on D that is orthogonal to segment st . We claim that one of the disks of any separating pair must cover either a or b . Indeed, assume on the contrary that there exists two unit disks D_1 and D_2 that separate s and t but do not contain neither a nor b (nor s or t). Without loss of generality, we may assume that both s and t lie on the boundary of D . Observe that in order to separate s and t , the union of D_1 and D_2 must cross segment st and cannot cross segment ab (otherwise it would contain s or t , since D , D_1 and D_2 are unit disks). However, the only possible way of doing so is if D_1 and D_2 are tangent to a , b and either s or t (see Figure 10). However, in this case s and t are not separated, a contradiction.

That is, for each separating pair we have a unique disk that covers either a or b . Since no point is contained in more than Δ disks (and D contains both a and b) we conclude that there cannot be more than $2(\Delta - 1)$ separating pairs, completing the proof of the lemma.

□

The previous lemma implies that in an optimal resilience path, if a disk appears twice, the two entry points have resilience at most $4\Delta - 3$ apart (when counting the cells traversed by the path between the two occurrences of the disk). Note that a lower bound of Δ is also easy to construct, so the result is (asymptotically speaking) tight.

To prove the result in this section it will be convenient to focus on the sequence of disks encountered by a path when going from p to q . It turns out that such problem is essentially a string problem, where each symbol represents a disk encountered by the path. In that context, the thickness will be equivalent

⁴By *disjoint* we refer to the identities of the disks, not to the regions they occupy.

Figure 10: Barring symmetric configurations, this is the only way of making two disks that cross the segment st (dashed line) and avoids the segment ab (solid line). However, in this case the disks D_1 and D_2 do not separate s and t .

2 to the number of symbols of the string (recall that we assume that p is not
3 contained in any disk), and the resilience to the number of distinct symbols.

4 Let $S = \langle s_1 \dots s_n \rangle$ be a string of n symbols from some alphabet \mathfrak{A} , such
5 that no symbol appears more than twice. Let T be a substring of S . We define
6 $\ell(T)$ to be the length of T , and $d(T)$ to be the number of distinct symbols in
7 T . Clearly, $\frac{1}{2}\ell(T) \leq d(T) \leq \ell(T)$. Let σ and k be two fixed integers such that
8 $\sigma < k$. We define the *cost* of a substring T of S to be:

$$\psi(T) = \begin{cases} \sigma & \text{if } T = \langle \mathbf{a}\tau\mathbf{a} \rangle \text{ for some } \mathbf{a} \in \mathfrak{A}, \text{ string } \tau \text{ s.t. } \mathbf{a} \notin \tau, \text{ and } \ell(T) > \sigma, \\ d(T) & \text{if } \ell(T) \leq k \text{ (and the first condition fails),} \\ \ell(T) & \text{otherwise.} \end{cases}$$

9 Note that, in the string context, d acts as the resilience, ℓ as the thickness,
10 and ψ is the approximation we compute. Intuitively, if T is short (i.e., length
11 at most k) we can compute the exact value $d(T)$. If T has a symbol whose two
12 appearances are far away we will use a “shortcut” and pay σ (i.e., for unit disk
13 regions, by Lemma 12, we have $\sigma = 4\Delta - 3$). Otherwise, we will approximate d
14 by ℓ .

15 Given a long string, we wish to subdivide S into a *segmentation* \mathcal{T} , composed
16 of m disjoint segments (i.e., substrings of S) T_1, \dots, T_m , that minimize the total
17 cost $\psi(\mathcal{T}) = \sum_i \psi(T_i)$. Clearly, $\psi(\mathcal{T}) \leq \ell(S)$.

18 **Lemma 13** *Let S be a string. There exists a segmentation \mathcal{T} such that $\psi(\mathcal{T}) \leq$*
19 *$(1 + \varepsilon)d(S)$, where $\varepsilon = 2\sqrt{\sigma/k}$.*

20 **Proof:** Let λ be an integer such that $\sigma < \lambda < k$, of exact value to be specified
21 later. First, we consider all pairs of equal symbols in S that are more than λ
22 apart. We would like to take all of these pairs as separate segments; however,
23 we cannot take segments that are not disjoint. So, we greedily take the leftmost
24 symbol \mathfrak{s} whose partner is more than λ further to the right, and mark this as a
1 segment. We recurse on the substring remaining to the right of the rightmost

Figure 11: (a) A string of 52 symbols, each appearing twice. (b) First, we identify a maximal set of *long* segments bounded by equal symbols, and longer than $\lambda = 4$ (shown in red). (c) Then, we segment the remaining pieces into *short* segments, with length $k = 10$ (shown in blue). Red symbols are double-counted.

2 \mathfrak{s} .⁵ Finally, we segment the remaining pieces greedily into pieces of length k .
3 Figure 11 illustrates the resulting segmentation. We will refer to the segments
4 of the first type, with length more than λ , as *long* segments. The remaining
5 segments, of length at most k , will be called *short*.

6 Now, we prove that the resulting segmentation has a cost of at most $(1 +$
7 $\varepsilon)d(S)$. First, consider a symbol to be *counted* if it appears in only one short
8 (blue) segment, and to be *double-counted* if it appears in two different short
9 segments. Suppose \mathfrak{s} is double-counted. Then the distance between its two
10 occurrences must be smaller than λ , otherwise it would have formed a long
11 (red) segment. Therefore, it must appear in two adjacent short segments. The
12 leftmost of these two segments has length exactly k , but only λ of these can
13 have a partner in the next segment. So, at most a fraction λ/k symbols are
14 double-counted.

15 Second, we need to analyze the cost of the long (red) segments. In the worst
16 case, all symbols in the segment also appear in another place, where they were
17 already counted. In this case, the true cost would be 0, and we pay σ too much.
18 However, we can assign this cost to the at least λ symbols in the segment;
19 since each symbol appears only twice they can be charged at most once. So,
20 we charge at most σ/λ to each symbol. The total cost is then bounded by
21 $(1 + \lambda/k + \sigma/\lambda)d(S)$. To optimize the approximation factor, we choose λ such
22 that $\lambda/k = \sigma/\lambda$; more precisely we take $\lambda = \lceil \sqrt{k\sigma} \rceil$. \square

23 Recall that for our resilience approximation we have $\sigma = 4\Delta - 3$ (Lemma 12).
24 Thus, the actual value of k is obtained by solving $\varepsilon = 2\sqrt{\sigma/k}$ for k , which leads
25 to $k = \lceil (16\Delta - 12)/\varepsilon^2 \rceil$.

26 4.2 Application to resilience approximation

27 We now show that the shortest path between any p, q in G_k is a $(1 + \varepsilon)$ -
28 approximation of their resilience. Let π be a path from p to q in \mathbb{R}^2 , and
29 let $S(\pi)$ be the sequence that records every disk of \mathcal{D} we enter along π , plus the
30 disks that contain the start point of π , added at the beginning of the sequence,
1 in any order. Then we have $|S(\pi)| = t(\pi)$.

⁵In fact, we could choose any disjoint collection such that after their removal there are no more segments of this type longer than λ .

Figure 12: (a) The optimal path ρ , achieving a resilience of 2. There is a segmentation of ρ of cost 3, using the dashed shortcut. (b) A minimum cost path π found by the algorithm. In this example, the resilience of π is 3.

Lemma 14 For every path π from p to q and every segmentation \mathcal{T} of $S(\pi)$, there exists a path from p to q in G_k of cost at most $\psi(\mathcal{T})$.

Proof: We describe how to construct a path in G_k based on \mathcal{T} . For every segment T of \mathcal{T} , we create a piece of path whose length in G_k is at most the cost of the segment $\psi(T)$.

There are three types of segments. The first type are segments that start and end with the same symbol \mathbf{a} , which corresponds to a disk $D \in \mathcal{D}$. For those, we make a shortcut path that stays inside D , as per Lemma 12. The second type are segments whose length is at most k . For those, by definition, G_k contains a shortcut edge whose cost is exactly the resilience between the corresponding cells of $\mathcal{A}(\mathcal{D})$. The third type are the remaining segments. For those, we simply use the piece of π that corresponds to T . \square

Lemma 15 For any $p, q \in \mathbb{R}^2$, it holds $\text{cost}_{G_k}(\mathfrak{P}_{G_k}(p, q)) \leq (1 + \varepsilon)r(p, q)$.

Proof: Let ρ be a path from p to q of optimal resilience $r^* = r(\rho) = r(p, q)$. Then, consider the sequence $S(\rho)$, that is, the sequence of disks that ρ enters. Now, by Lemma 13, there exists a segmentation \mathcal{T} of $S(\rho)$ of cost at most $(1 + \varepsilon)d(S(\rho)) = (1 + \varepsilon)r^*$. By Lemma 14, there exists a path in G_k of equal or smaller cost. Figure 12 illustrates this.

Now, consider the path π that our algorithm produces. The resilience of π is smaller than the cost of π in G_k , which is smaller than the cost of ρ in G_k , which is smaller than $1 + \varepsilon$ times the resilience of ρ . That is: $r(\pi) \leq \text{cost}_{G_k}(\pi) \leq \text{cost}_{G_k}(\rho) \leq (1 + \varepsilon)r(\rho) = (1 + \varepsilon)r^*$. \square

Theorem 3 Let \mathcal{D} be a set of unit disks of ply Δ in \mathbb{R}^2 . We can compute a path π between any two given points $p, q \in \mathbb{R}^2$ whose resilience is at most $(1 + \varepsilon)r(p, q)$ in $O(2^{f(\Delta, \varepsilon)}n^5)$ time, where $f(\Delta, \varepsilon) = O\left(\frac{\Delta^2 \log(\Delta/\varepsilon)}{\varepsilon^4}\right)$.

Proof: The running time of the algorithm is dominated by the preprocessing stage: determining if the resilience between every pair of vertices of $G_{\mathcal{A}(\mathcal{D})}$ is at

2 most $\lceil (16\Delta - 12)/\varepsilon^2 \rceil$. Since $G_{\mathcal{A}(\mathcal{D})}$ is an arrangement of disks with ply at most
3 Δ , it has $O(\Delta n)$ cells⁶. We execute the algorithm of Theorem 1 for every pair
4 of cells (thus, $O(\Delta^2 n^2)$ times), and we obtain the desired bound. \square

5 4.3 Extension to fat regions

6 As in Section 3.2, we now generalize the result to arbitrary β -fat unit regions.
7 We again assume that our collection of regions has bounded ply Δ , and that
8 the region boundaries have $O(1)$ pairwise intersections. As in Section 3.2, for
9 simplicity in the notation our analysis assumes that the region boundaries have
10 at most two pairwise intersections, implying that the intersection between any
11 two overlapping regions has one connected component. However, our results
12 generalize to $k = O(1)$ pairwise intersections between region boundaries.

13 **Lemma 16** *Let $D \in \mathcal{D}$, where $\mathcal{A}(\mathcal{D})$ has ply Δ , and let p, q be any two points*
14 *inside D . Then the resilience between p and q in \mathcal{D} is at most $(2\beta + 1)^2 \Delta$.*

15 **Proof:** The resilience between p and q is upper-bounded by the number of
16 regions that intersect D . We can give an upper bound using a simple packing
17 argument. Since p and q belong to a β -(unit)fat region D , they are both inside
18 a circle C with center c and radius β . Any other β -fat region D' that interferes
19 with the path from p to q must intersect C . Such an intersecting region, being
20 also β -fat, must contain a unit-disk whose center cannot be more than 2β away
21 from c . Therefore all regions intersecting C have their unit-disks centered at
22 distance at most β from c . Moreover, such disks are totally contained in a disk
23 of radius $2\beta + 1$ centered at c . As in the proof of Lemma 7, we can show that
24 at most $(2\beta + 1)^2$ disjoint unit-disks fit into a disk of radius $(2\beta + 1)$. Since the
25 ply is at most Δ , the maximum number of unit-disks inside a disk of radius β
26 in \mathcal{D} is $(2\beta + 1)^2 \Delta$. \square

27 As before, the rest of the arguments do not rely on the geometry of the
28 regions anymore, and we can proceed as in the disk case. The only difference is
29 that the value σ of doing a shortcut has increased to $(2\beta + 1)^2 \Delta$.

30 **Theorem 4** *Let \mathcal{D} be a set of β -fat regions of ply Δ in \mathbb{R}^2 . We can compute a*
31 *path π between any two points $p, q \in \mathbb{R}^2$ whose resilience is at most $(1 + \varepsilon)r(p, q)$*
32 *in $O(2^{f(\Delta, \beta, \varepsilon)} n^5)$ time, where $f(\Delta, \beta, \varepsilon) = O\left(\frac{\Delta^4 \beta^8}{\varepsilon^4} \log(\beta \Delta / \varepsilon)\right)$.*

33 5 NP-hardness

34 In this section we show that computing the resilience of certain types of fat
35 regions is NP-hard. We recall that several NP-hardness results for other shapes
36 are already known, but most of them are for skinny objects. For example,
1 hardness for the case in which regions are line segments in \mathbb{R}^2 was shown in [2, 23]

⁶We thank the anonymous referee that pointed this to us and allowed the dependency in n to be lowered.

Figure 13: (a) A planar odd embedded graph. (b) A non-planar one. (c) A tripartite graph, oddly embedded around p .

and [26, Section 5.1]. Our contribution is to show that hardness holds for the case in which ranges have bounded fatness (i.e., ranges are not skinny). The only hardness proof that we know for objects of positive area is by Tseng [22], who shows that if the regions are rotations and translations of a fixed square or ellipse the problem is NP-hard.

In addition to showing that the problem is difficult for other shapes, our construction is of independent interest, since it is completely different from those given in [2], [22], [23], and [26, Section 5.1]. Moreover, our proof has the advantage of being easy to extend to other shapes. We also note that the construction of Tseng uses several rotations of a fixed shape (i.e., 3 for a square, 4 for an ellipse), whereas our construction only needs two different rotations of the same shape.

First we show NP-hardness for general connected regions, and later we extend it to axis-aligned rectangles of aspect ratio $1 : 1 + \varepsilon$ and $1 + \varepsilon : 1$. We start the section establishing some useful graph-theoretical results.

Let G be a graph, and let p be a point in the plane. Let Γ be an embedding of G into the plane, which behaves properly (vertices go to distinct points, edges are curves that do not meet vertices other than their endpoints and do not triple cross), and such that p is not on a vertex or edge of the embedding. We say Γ is an *odd* embedding around p if it has the following property: every cycle of G has odd length if and only if the winding number of the corresponding closed curve in the plane in Γ around p is odd. We say a graph G is *oddly embeddable* if there exists an odd embedding Γ for it (Figure 13 shows some examples). We claim that vertex cover is NP-hard for this constrained class of graphs. The proof of this statement is based on two observations.

Observation 1 *Every tripartite graph is oddly embeddable.*

Proof: The vertices of a tripartite graph G can be divided into three groups V_1, V_2, V_3 such that there are no internal edges in any of these groups. Now, consider a triangle Δ around p . We create an embedding Γ where all vertices in

2 V_1 are close to one corner of Δ , the vertices in V_2 are close to a second corner,
3 and the vertices in V_3 are close to the remaining corner. All edges are straight
4 line segments. See Figure 13(c).

5 Consider the graph H obtained from G by contracting all vertices in V_i to
6 a single vertex v_i ; H is a triangle (or a subgraph of a triangle). Now consider
7 any cycle in G , and project it to H . Since there were no edges in G connecting
8 vertices within a group V_i , this does not change the length of the cycle, nor
9 does it change the winding number around p . Any two consecutive edges from
10 v_i to v_j , and back from v_j to v_i , do not influence the parity of the length of
11 the cycle, nor the winding number around p , so we can remove them from the
12 cycle. We are left with a cycle of length $3w$ and winding number w or $-w$, for
13 some integer w . Clearly, $3w$ is odd if and only if w is odd. Therefore, Γ is an
14 odd embedding of G , as required. \square

15 The *maximum independent set* problem in a graph asks for the largest set
16 of vertices in the graph such that no two vertices in the set are connected by an
17 edge. This problem is well-known to be NP-hard on general graphs. In fact, it
18 remains NP-hard for tripartite graphs. A simple proof is included for complete-
19 ness, and because we need the argument later. Note that a minimum vertex
20 cover is the complement of a maximum independent set, hence by proving the
21 NP-hardness of maximum independent set, we are also proving that minimum
22 vertex cover is NP hard.

23 **Observation 2** Let $G = (V, E)$ be a graph, and G' be the tripartite graph ob-
24 tained from G by subdividing every edge $e \in E$ into an odd number of pieces m_e .
25 Let $m = \sum_e m_e$ be the total number of vertices added. Let I and I' be maximum
26 independent sets of G and G' , respectively. Then, it holds that $|I'| = |I| + m/2$.

27 **Proof:** For every independent set $I \subseteq V$ in G , there is a corresponding
28 independent set I' in G' with $|I'| = |I| + m/2$: for every pair of extra vertices on
29 an edge, we can always add one of the two to an independent set. Conversely,
30 for every independent set I' in G' , there is a corresponding independent set I
31 in G with $|I| = |I'| - m/2$: I' cannot use both extra vertices on an edge, so
32 if we simply remove all extra vertices we remove at most $|E|$ elements from I'
33 (clearly, if we remove less than $m/2$ vertices from I' this way, we can remove
34 more vertices until I has the desired cardinality). \square

35 From the above observations, it follows that maximum independent set is
36 also NP-hard on tripartite graphs, and hence, also on oddly embeddable graphs.
37 Since our construction does not increase the maximum vertex degree, and vertex
38 cover is known to be NP-hard for graphs with maximum degree three, we obtain
39 the following.

40 **Corollary 3** Minimum vertex cover on oddly embeddable graphs of maximum
41 degree 3 is NP-hard.

42 Given an embedded graph Γ , we say that a curve in the plane is an *odd Euler*
1 *path* if it does not go through any vertex of Γ and it crosses every edge of Γ an
2 odd number of times.

Figure 14: (a) An oddly embedded graph with four crossings. (b) The crossings are flattened according to the parity of their vertices. (c) An odd Euler path from p to the outer face.

Lemma 17 *Let p be a point in the plane, and Γ an oddly embedded graph around p . Then there exists an odd Euler path for Γ that starts at p and ends in the outer face. Moreover, such path can be computed in polynomial time.*

Proof: First, we insert an even number of extra vertices on every edge of Γ such that in the resulting embedded graph Γ' , every edge crosses at most one other edge. Now we construct an Euler path that crosses every edge of Γ' exactly once; note that this path will therefore cross every edge of Γ an odd number of times. Consider a pair of crossing edges and the four vertices concerned. For each pair of consecutive vertices (vertices that are not endpoints of the same edge), find a path in the graph that does not go around p (when seen as a cycle, after adding the crossing).

The parity of the length of this path does not depend on which path we take: if there would be an even-length path and an odd-length path between the same two vertices, both of which do not go around p , then there would be an odd cycle that does not contain p , which contradicts the oddly embeddedness of Γ' . Now, if the path has even length, we identify these two vertices. Note that of the four pairs of vertices involved in a crossing (i.e., ignoring the two pairs forming edges in Γ), exactly two pairs will have odd length connecting paths, so effectively we “flatten” the crossing. We do this for all crossings, and call the resulting multigraph Γ'' . See Figure 14(b). (If the two crossing edges belong to different connected components of Γ , there are no paths connecting their vertices; in this case we make an arbitrary choice of which vertices to identify.)

Now Γ'' is planar. Furthermore, by construction, all faces of Γ'' have even length, except the one containing p and the outer face. Therefore, the dual multigraph of Γ'' has only two vertices of odd degree, and hence has an Euler path between these vertices. Furthermore, this Euler path crosses every edge of Γ' exactly once, and therefore every edge of Γ an odd number of times. Note that the proof is constructive. Moreover, both the transformations and the Euler path can be done in polynomial time, hence such path can also be obtained in polynomial time. \square

Figure 15: Creating regions to follow Γ and T .

Lemma 18 *Let p be a given point in the plane, and Γ an oddly embedded graph (not necessarily planar) around p . Furthermore, let T be a curve that forms an odd Euler path from p to the outer face. Then we can construct a set \mathcal{D} of connected regions such that a minimum set of regions from \mathcal{D} to remove corresponds exactly to a minimum vertex cover in Γ .*

Proof: If T is self-intersecting, then we can rearrange the pieces between self-intersections to remove all self-intersections. Thus we assume that T is a simple path.

If T crosses any edge of Γ more than once, we insert an even number of extra vertices on that edge such that afterwards, every edge is crossed exactly once. Let Γ' be the resulting graph. Since we inserted an even number of vertices on every edge, finding a minimum vertex cover in Γ' will give us a minimum vertex cover in Γ .

Now, for each vertex v in Γ' , we create one region D_v in \mathcal{D} . This region consists of the point where v is embedded, and the pieces of the edges adjacent to v up to the point where they cross T . Figure 15(a) shows an example (the regions have been dilated by a small amount for visibility; if the embedding Γ has enough room this does not interfere with the construction). Note that all regions are simply connected.

Finally, we create one more special region W in \mathcal{D} that forms a corridor for T . Then W is duplicated at least n times to ensure that crossing this “wall” will always be more expensive than any other solution. Figure 15(b) shows this.

Now, in order to escape, anyone starting at p must roughly follow T in order to not cross the wall. This means that for every edge of Γ' that T passes, one of the regions blocking the path (one of the vertices incident to the edge) must be disabled. The smallest number of regions to disable to achieve this corresponds to a minimum vertex cover in Γ' . \square

Combining this result with Corollary 3, we obtain our first hardness result for the barrier resilience problem.

Theorem 5 *The barrier resilience problem for a collection of connected regions*

3 *is NP-hard.*

4 5.1 Extension to fat regions

5 We now adapt the previous approach to also work for a much more restricted
6 class of regions: axis-aligned rectangles of sizes $1 \times (1 + \varepsilon)$ and $(1 + \varepsilon) \times 1$ for
7 any $\varepsilon > 0$ (as long as ε depends polynomially on n). For simplicity, we limit
8 Γ to have maximum degree 3. Maximum independent set is still known to be
9 NP-hard in that case [10], and making them tripartite does not change the
10 maximum degree.

11 The idea of the reduction is the following. We start from a sufficiently
12 spacious (but polynomial) embedding of Γ , as illustrated in Figure 16(a). On
13 each edge we add a large even number of extra vertices. Each new vertex
14 will be replaced by a rectangle, so every edge in Γ will become a chain of
15 overlapping rectangles, like the green rectangles in Figure 16(b). Therefore the
16 first phase consists in replacing the embedding of Γ by an equivalent embedding
17 of rectangles. We call these rectangles *graph rectangles* (green in the figures).
18 Some care must be taken in the placement of graph rectangles around degree-3
19 vertices and in crossings, so that the rest of the construction can be made to
20 work. Next, we place *wall rectangles* (orange in the figures; these consist of many
21 copies of the same rectangle) across each graph rectangle. The gaps between
22 adjacent wall rectangles should cover the overlapping part of two adjacent graph
23 rectangles, so that a path can pass through them only whenever one of the
24 two graph rectangles is removed. Then, we find a curve T from p that goes
25 through every gap exactly once (note that T exists, by Lemma 17). Figure 16(c)
26 illustrates this phase of the construction. Finally, we add more wall rectangles
27 around T , to force any potential minimum resilience path from p that does not
28 go through the wall rectangles to be homotopic to T . Figure 16(d) shows the
29 final set of rectangles. Now, computing an optimal resilience path among this
30 set of rectangles would correspond to a maximal independent set in Γ .

31 For the construction to work, there needs to be enough space to place the wall
32 rectangles. It is clear that this is possible far away from the graph rectangles,
33 but close to the graph rectangles we proceed as follows: first, Figure 17(a)
34 shows the placement of rectangles along an edge of Γ . Figure 17(b) shows how
35 to place the rectangles at degree-3 vertices. Crossings are handled as shown in
36 Figure 17(c). These gadgets force some of the gaps in the chain to join each
37 other. But this is no problem if every edge has enough rectangles. Also, note
38 that at the center of the construction in Figure 17(c) there are two overlapping
39 green rectangles, which belong to the two crossing chains. This is the only place
40 where we vitally use the fact that the regions are not pseudodisks.

41 **Lemma 19** *Let p be a given point in the plane, and Γ an oddly embedded graph*
42 *with maximum vertex degree 3 (not necessarily planar) around p . Furthermore,*
43 *let T be a curve that forms an odd Euler path from p to infinity. Then we can*
1 *construct a set \mathcal{D} of axis-aligned rectangles of aspect ratio $1 : (1 + \varepsilon)$ such that*

Figure 16: (a) A non-planar oddly embedded cubic graph, embedded on a grid. (b) A set of rectangles, containing exactly one rectangle for each input vertex, and an even number of rectangles for each input edge. Note that crossings can be embedded if sufficiently far apart. (c) Local walls are added to make “tunnels”, each tunnel contains the overlapping part of two adjacent yellow rectangles. To go through a tunnel, one of the two yellow rectangles has to be removed. Then we choose an Euler path from p to the outside, that goes through each tunnel exactly once. (d) The final set of rectangles, designed to force any path from p to the outside to be homotopically equal to the one we drew.

Figure 17: Local details of the construction. Note that we use rectangles with a large aspect ratio for visibility, but the same constructions can be made with aspect ratio arbitrarily close to 1. (a) Overlapping rectangles to create edges (with an even number of extra vertices). (b) A vertex of degree at most 3, which is just a single rectangle. (c) A crossing between two chains.

2 *a minimum set of regions from \mathcal{D} to remove corresponds exactly to a minimum*
3 *vertex cover in Γ .*

4 **Proof:** We first add groups of extra vertices on every edge of Γ so that we
5 have room to place the rectangles, in an even number per edge. Then replace
6 edges by chains as of rectangles as as in Figure 17, and connect the orange
7 (wall) rectangles to force the only optimal path from p to the outer face to be
8 along the Euler path T . The path may have to be rerouted locally close to the
9 crossings, but since there is a sufficiently large number of crossings with every
10 edge anyway, this is always possible. Orange rectangles have to be duplicated
11 sufficiently many times again, to make sure that no optimal path will ever cross
12 them. \square

13 **Theorem 6** *The barrier resilience problem for regions that are axis-aligned*
14 *rectangles of aspect ratio $1 : (1 + \varepsilon)$ is NP-hard.*

15 A similar approach can likely be used to show NP-hardness of other classes
16 of regions as well. However, it seems that a necessary property for our approach
17 is that the regions are able to completely cross each other: in other words, the
18 regions in \mathcal{D} cannot be pseudodisks.⁷
